INTRODUCTION

Colorectal cancer is the second most common cancer in the world and has aggressive malignancy, with a high tendency to deep invasion, lymph node metastases, and distant metastases [1]. Due to its frequent diagnosis, usually only at an advanced stage, the reported incidence of colon cancer increases remarkably each year. In the year 2020, colorectal cancer ranked third as the most common type of cancer diagnosed worldwide, with approximately 1.9 million new cases and causing 930,000 deaths. Epidemiological projections indicate that by the year 2040, the incidence of this type of cancer will increase significantly, reaching about 3.2 million new cases annually, while associated mortality is expected to increase to 1.6 million deaths per year [2]. It also holds the second position in cancer-related deaths and is the main contributor to cancer-related deaths in men under 50 years of age. More than half of all colorectal cancer cases can be attributed to modifiable risk factors such as tobacco use, an unhealthy eating pattern, excessive alcohol consumption, lack of physical activity, and obesity [3]. A substantial number of cases of colorectal cancer and mortality can be avoided through regular *screening*, vigilant monitoring and access to high-quality medical care [4]. *Serum markers* (indicators) such as carcinoembryonic antigen (CEA) and cancerous antigen 19-9 (CA 19-9) have low specificity and sensitivity [5]. Colonoscopy, one of the most available diagnostic methods, has a high degree of invasiveness [6].

The main objective of this doctoral thesis is to use relaxometry and diffusiometry measurements of ^1H MRI in low magnetic fields, high-resolution ^1H MRI spectroscopy as well as FT-IR spectroscopy, for the identification of specific characteristics sensitive to the presence of features (*markers*) colorectal cancer in native and deproteinised blood plasma and blood plasma proteins, as well as MRI spectroscopy and imaging in high magnetic fields to characterise healthy tissues or tissues affected by colorectal cancer or other materials of biological origin. For this, the raw data are analyzed by numerical procedures involving the deconvolution (of the FT-IR spectra) and the inverse Laplace transform (of the fall curves of the type CPMG and PGSE by MRI of ^1H) to obtain the distributions of the transverse relaxation time, T_2 and the self-diffusion coefficient D . The relevant parameters were used as input data for the PCA analyses and the most important physical properties (the parameters describing the physical systems studied), blood samples or biopsies taken from colorectal cancer patients or from samples taken from healthy volunteers are identified.

CHAPTER 1 Physiology of Blood

General

Blood is a fundamental component of human life [7] made up of several types of components with very diverse properties and is often called a *liquid organ* [8]. In the body of an adult, about 4 to 5 liters of blood circulates continuously through a complex network of vessels, propelled by the strong contractions of the beating heart [7], and its distribution, through the vascular system, throughout the body is essential for the existence of the body [8].

Fig. 1.1 A small blood sample is collected in a biochemistry tube and centrifuged to separate the plasma cells [after reference 9].

1.2 Blood components

Blood is made up of two main parts, namely blood cells [8] which are also called figurative elements [10] and which are synthesized mainly in bone marrow and blood plasma, or the liquid part of blood [8]. The figured elements can be separated from the plasma by placing a blood sample in a tube and centrifuging it for several minutes. Because red blood cells are denser than blood plasma, they are deposited at the base of the tube and usually make up about 45% of the total volume. This value is referred to as hematocrit. The white blood cells and platelets form a thin, cream-colored area called the leukocyte layer, located just above the red blood cells. At the top of the tube is plasma, which is pale yellow in colour and accounts for almost 55 % of the total volume [9].

1.2.1 *Colorectal cancer*

Colorectal cancer (CRC) is one of the most common types of cancer in Western countries and, increasingly, globally [11]. It is the second leading cause of cancer death worldwide [12], and the most common in both sexes [13, 14], with cancer taking nearly one million lives in 2020 [12]. There are several modifiable risk factors associated with CRC, and in the case of well-defined hereditary syndromes, which include CRC as a manifestation, germline genetic mutations have been identified. Polyps, especially adenomas, are recognized preneoplastic lesions, and their accessibility through endoscopy allows both early detection and effective diagnosis and treatment [11]. Over the course of a lifetime, the risk of developing colorectal cancer (hereinafter referred to as CRC or CRC) in patients at average risk is about 5%, and in 90% of cases, the disease occurs after the age of 50. Unfortunately, almost a third of people diagnosed with CRC die from this condition. Although the early forms of the disease are often curable by surgery, in the advanced stages, when metastases are present and surgical treatment is no longer an option, the prognosis becomes severe and the course is fatal. These aspects underline the importance of effective screening and monitoring programmes, which are essential for the early detection of the disease. In addition, identifying and managing premalignant lesions is a crucial step in preventing the development of colorectal cancer [13].

Risk factors for colorectal cancer are both genetic and environmental in nature, and they play a key role in determining how the disease presents itself, being classified into three types: sporadic, inherited and familial. Sporadic cases, in which there is no family history of cancer, account for about 70% of all CRC cases. Usually, patients with this form are older than 50 years old, and the etiological factors involved are those related to diet and the environment. However, genetic changes have also been identified that lead to the progression of the disease from adenoma to carcinoma [15]. In less than 10% of patients, there is an inherited genetic predisposition for CRC, and these cases can be divided according to the presence or absence of colon polyps as the main manifestation. Polyposis diseases include familial adenomatous polyposis (FAP) and hamartomatous polyposis syndromes such as Peutz-Jeghers syndrome and juvenile polyposis [16], while non-polyposis diseases are hereditary non-polyposis colorectal cancer (also known as Lynch I syndrome) and familial cancer syndrome (Lynch II syndrome) [17]. The third type of colorectal cancer, the least understood to date, is known as familial colorectal cancer. Almost 25% of affected patients have a family history of colorectal cancer, but their pattern (structure) does not correspond to those described in the aforementioned inherited syndromes. People from these families have a higher risk of developing colorectal cancer.

1.3 Methods of separation of blood components

The separation of blood components is an essential step in biochemical and metabolic analysis, being necessary for investigating plasma composition and identifying relevant metabolites in various pathologies [18].

Stages I - Processing of blood samples

- a) *Sampling from patients.* Blood samples are taken under aseptic conditions, using the venipuncture technique. A disposable needle and a vacuum or syringe collection system are used.
- b) *Transfer of blood to the test tube.* The collected blood is immediately distributed in specific test tubes, depending on the type of analysis required. Biochemistry test tubes without anticoagulant are used to obtain the serum.
- c) *Preparing the test tube for spinning.* The test tubes are inverted several times for blood homogenization and are then placed in a suitable holder, ready for centrifugation. Tubes without anticoagulant are left to stand at room temperature for 30–60 minutes.
- d) *Centrifugation of samples.* The test tubes are placed in a balanced centrifuge, with tightly closed lids, and are subjected to centrifugation according to the protocol. The centrifugation parameters vary depending on the desired component, as follows: i) For plasma separation: 2000–3000 rpm for 10–15 minutes at 4°C; ii) Separation of blood fractions.
- e) *Following centrifugation,* the samples are separated into distinct fractions: i) Plasma or serum – the clear, upper layer used for biochemical and metabolomic analyses; ii) Buffy coat – the intermediate, whitish layer containing leukocytes and platelets (used for DNA isolation or immunological analysis) and iii) Figurative elements (erythrocytes, leukocytes, platelets) – the lower, compacted layer.
- f) *Plasma/serum collection.* The plasma or serum is carefully extracted using a micropipette or automatic pipette, without disturbing the buffy coat or erythrocyte mass. The sample is transferred to sterile tubes and stored at the appropriate temperature (-80 °C for long-term storage or 4 °C for immediate analysis).

Steps II - Processing of plasma samples

- a) *Transfer of plasma into microtubes (Eppendorf).* The plasma obtained after the initial centrifugation is transferred using a micropipette to a sterile Eppendorf microtube, ensuring gentle handling of the sample to avoid contamination or hemolysis.

-
- b) Plasma sampling for protein precipitation.* A 100 μL volume of plasma is precisely pipetted and transferred to a 1.5 mL Eppendorf microtube for the deproteinization step.
- c) Adding solvent for protein precipitation.* In the same Eppendorf microtube, 900 μL of cold methanol is added to obtain a 1:9 plasma/methanol ratio, favorable to protein precipitation. The mixture is homogenized by gentle vortexing for a few seconds.
- Preparation of samples for centrifugation.* The Eppendorf microtubes containing the plasma-methanol mixture are placed in a larger test tube (15 or 50 mL, depending on the centrifuge configuration) to ensure rotor balancing and mechanical protection of the samples during centrifugation.
- d) Introduction of microtubes into the centrifuge.* The microtubes are symmetrically distributed in the centrifuge rotor to prevent mechanical imbalance. Check the correct positioning and close the centrifuge lid.
- e) Centrifugation for separation of plasma fractions.* The centrifugation of the samples is performed at 4°C, at a relative centrifugal force (RCF) of 2000 g, for 10-15 minutes. This process causes the precipitated proteins (which are deposited at the bottom of the microtube) to separate from the clear supernatant.
- f) Separation of supernatant from precipitate.* After centrifugation, the samples are handled carefully to avoid resuspension of the protein precipitate. The supernatant (clear liquid layer) is separated with a micropipette and transferred to a new, sterile Eppendorf microtube.
- g) Supernatant collection (deproteinized plasma).* The supernatant, which contains soluble metabolites and other non-protein components, is retained for further analysis, such as MRI spectroscopy or FT-IR spectroscopy. It can be stored temporarily at -20 °C or long-term at -80 °C to prevent degradation of volatile compounds.
- h) The resulting protein sediment.* The protein precipitate, visible as a whitish deposit at the base of the microtube, can be removed or used for further proteomic analysis if necessary.

CHAPTER 2 METHODS OF ANALYSIS AND MATERIAL RESOURCES

2.1 Nuclear magnetic resonance

2.1.1 General principles

Spectroscopy is an advanced method of studying various types of materials that provides detailed information based on examining the specific way matter interacts with electromagnetic radiation. Atoms and molecules are known to exhibit a series of discrete energy levels, which correspond to the electronic, vibrational or rotational states that are quantized. The interaction occurs through the absorption and emission of photons (in the visible domain or adjacent domains), where the energy of the photons matches the energy difference between two energy states. Because the energy of a photon (generally of a radiation quantum) is directly related to its frequency. Thus, the different types of spectroscopy are usually defined based on the frequencies of the specific electromagnetic radiation involved in the interaction process. The processes of absorption and emission of radiation lead to transitions between the electronic states of the outer electrons and usually involve frequencies in the ultraviolet (UV) range, leading to UV spectroscopy. Molecular vibration modes are characterized by frequency values just below those of red light in the visible range and are thus analyzed using infrared (IR) spectroscopy. Otherwise, nuclear magnetic resonance spectroscopy (NMR for short) uses frequencies in the radio wave range, usually in the range of 10 to 1000 MHz [19].

2.1.2 NMR proton relaxometry

The CPMG (Carr-Purcell-Meiboom-Gill) pulse sequence is widely used in the world, especially when using MRI relaxometry techniques, to rapidly obtain (*single shoot*) MRI signal drops that contain information about molecular dynamics on a time scale covering several orders of magnitude and that are suitable for characterizing most liquid and soft solid organic samples or biological tissues. The fall of the train of multiple echoes that occur in the CPMG in measurements made in homogeneous, or even inhomogeneous, magnetic fields is generated by a combination of stimulated echoes and Hahn.

Multi-exponential analysis of CPMG data

In recent years, various algorithms have been developed that more or less efficiently perform the inverse Laplace transform of experimental data [20, 21-25]. This is a badly conditioned problem so the data must be regularized to make the effects of noise. To date, the inverse Laplace transform has been applied in NMR mostly for isolated spine systems such as fluids in porous media [21-23, 26, 27] or food samples [27] and free-to-diffuse molecules [22, 24, 26-28].

A data inversion algorithm (by inverse Laplace-type transform) was described in references [21, 29] was used in the experimental part of this thesis for data processing and obtaining a normalized distribution of the transverse relaxation time T_2 , which is denoted by $f(T_2)$ and is related to the magnetization of the spin system by,

$$M(\tau) = \int_0^{\infty} f(T_2) e^{-\frac{\tau}{T_2}} dT_2, \quad (2.1)$$

2.1.3 Localized high-field ^1H MRI spectroscopy

Nuclear magnetic resonance spectroscopy is possible for any nucleus that possesses a magnetic moment (the nuclear spin must be non-zero). For *in vivo* applications of magnetic resonance spectroscopy, metabolic nuclei with a high degree of interest that have this property are proton (^1H), carbon-13 (^{13}C), phosphorus (^{31}P) and sodium (^{23}Na). Although the number of relevant nuclei is limited, each nucleus provides a large amount of information, as a large number of metabolites can be detected simultaneously. Magnetic resonance spectroscopy of ^1H allows the detection of important neurotransmitters, such as glutamate, GABA or aspartate, together with related compounds, such as glutamine, and the end product of glycolysis, lactate. ^{13}C offers the possibility to study *in vivo* but non-invasively complex flows through important metabolic pathways, such as the tricarboxylic acid cycle. ^{31}P spectroscopy provides information on energy-important metabolites, intracellular pH, magnesium concentration and reaction flows. In addition to the mentioned nuclei, MRS magnetic resonance spectroscopy or *in vivo* may also become relevant for other nuclei in special cases, such as helium (^3He), lithium (^7Li), nitrogen (^{15}N), oxygen (^{17}O), fluorine (^{19}F), silicon (^{29}Si) and potassium (^{39}K) [19].

2.2 Spectroscopia FT-IR

2.2.1 General principles

Fourier transform infrared spectroscopy (FT-IR) is a widely used technique for identifying functional groups in materials, whether gaseous, liquid or solid, using infrared (IR) radiation. Infrared spectroscopy measures the absorption of IR radiation by each bond in a molecule, resulting in a spectrum usually represented as absorbance (dimensionless) or transmittance (%) versus wavenumber (cm^{-1}). A variety of covalently bonded materials absorb electromagnetic radiation in the IR region, which has a lower energy and longer wavelength than light (visible range electromagnetic radiation) or UV radiation (which are used together in UV-VIS spectroscopy), but a higher energy and shorter wavelength than microwave radiation. In order for a molecule to be identified by its functional groups using IR spectroscopy, it must be active in IR,

i.e. it must have a dipole moment (non-zero). When IR radiation interacts with the covalent bonds of materials that have an electric dipole, the molecule absorbs energy, causing the chemical bond to oscillate. This oscillation, which modifies the net dipole moment of the molecule, is what allows the absorption of IR radiation [30]. The interaction of electromagnetic radiation with the substance is expressed in two ways: i) by the absorption, emission or dispersion of electromagnetic waves, and ii) by temporary or permanent changes in the optical, magnetic, thermal or chemical properties of the substance, regardless of whether it is made up of atoms, molecules, ions or other chemical entities [31]. The interaction of substances with any part of the electromagnetic spectrum is called spectroscopy, which is an analysis between matter and electromagnetic radiation in any field. The electromagnetic spectrum is made up of several types of radiation that include various wavelengths, being a form of radiant energy, starting from gamma rays and X-rays, passing through UV radiation, visible light, infrared, microwave and up to radio waves, each of which can be seen as a wave or particle that moves at the speed of light.

2.3 Material resource

In order to carry out this study, a close collaboration was carried out with the medical team from the Surgery I Department, which contributed to the collection of biological samples, ensuring adequate storage conditions and maintaining their integrity until the sampling and processing stage in order to obtain the final form for analysis.

2.3.1 Patients with colorectal cancer

In this study, all patients provided written informed consent, being fully informed about the objectives of the research and the specific procedures for collecting biological samples. The selection of patients diagnosed with colorectal cancer was based on a diagnosis confirmed by high-resolution imaging, including pelvic magnetic resonance imaging (MRI) and echo-endoscopy. For studies I and II, a total of 31 patients with histopathologically confirmed diagnosis, aged 35 to 81 years, were included. The exclusion criteria targeted patients who required emergency surgery. The study was conducted at the Cluj-Napoca County Clinical Hospital, Surgery I Department.

2.3.2 Healthy volunteers

Similar to patients diagnosed with colorectal cancer, volunteers in the control group received and signed informed consent to participate in the study. The criteria for inclusion in this group have been rigorously defined to ensure an appropriate comparison with the patient group. Thus, participants in the control group did not have a diagnosis of colorectal cancer, had ages and gender distribution comparable to those of cancer patients, and had no history of significant gastrointestinal disorders such as Crohn's disease, ulcerative colitis, advanced polyps, or

predisposing genetic syndromes, such as Lynch syndrome. Individuals with a history of pre-existing neoplastic diseases were also excluded.

Table 2.1 Some extensive characteristics (label, age, sex, environment of origin, RCT – radiochemically treated, diagnosis, histological grade, cancer staging, pn – regional lymph nodes) specific to patients with colorectal cancer.

CHAPTER 3 CHARACTERIZATION OF BLOOD PLASMA BY RELAXOMETRY AND DIFFUSION MRI

3.1 Pilot Study 1

3.1.1 Distributions of spin-spin relaxation times, T_2

Blood has two major plasma components that contain more than 90% water and blood cells. This component is well reflected in specific relaxation times. Figure 3.1 shows the distributions of T_2 transverse relaxation times measured for blood plasma collected from three healthy volunteers and 7 colorectal cancer patients. In Figure 3.1a, a number of four peaks can be observed. *The main peak* is located at a T_2 value of slightly less than 1 s, which indicates that the largest amount of ^1H is found in the water in the blood plasma. The center and width of this *peak* are affected by dissolved substances. This is indicated by the fact that the T_2 value is less than 2 s compared to the 3 s characteristic of distilled water. In addition to this main *peak*, there are three other secondary peaks located at i) about 0.9 to 1.3 ms that are associated with relatively immobile components; ii) another *peak* located at approximately 3.4 – 4.1 ms, which is associated with components with reduced mobility; and iii) another *peak* located at approximately 14.2 – 17.6 ms, which may be associated with components with medium mobility. *The main peak* is not very well defined. It has an asymmetrical shape and presents, at higher T_2 values, an elongated tail. Thus, the echo time (TE) value of 70 μs that was used in the CPMG pulse sequence must be increased. A different value of the echo time (TE = 0.5 ms) was used, and that resulted in two effects. First, an increased TE value will have a filtering effect on components with a shorter relaxation time (see Figure 3.1b). Therefore, it can be seen that components with relaxation times around 1 ms disappear. Secondly, a better definition of the main *peaks* located at about 731 - 771 ms is observed, and what was the desired effect. There is a great similarity between the distributions of T_2 measured for the three volunteers, as the values of T_2 differ slightly. Figure 3.1c shows the distributions of relaxation times obtained using the inverse Laplace transform of the CPMG signal drop curves measured with an echo time of 70 ms, for a number of seven patients with colorectal cancer. A main peak can also be observed, located at T_2 values below one second, between ~581 ms to 761 ms. Again, for a more accurate measurement of the position of the main peak, a second set of measurements were made with an echo time of 0.50 ms, and the corresponding distributions are shown in Figure 3.1d. Visually, no major changes are observed when comparing the transverse relaxation time (T_2 distributions) measured in the native blood plasma of cancer patients with those measured for healthy volunteers.

Fig.3.1. T_2 relaxation time distributions measured for native blood plasma harvested from V1-V3 healthy volunteers (top, a and b) and colorectal cancer patients (bottom – c and d) with echo time of $TE = 70 \mu s$ (left) and $TE = 500 \mu s = 0.50 \text{ ms}$ (right).

3.1.2 Distributions of the self-diffusion coefficient, D

The self-diffusion coefficient of blood molecules (especially water molecules) is an important parameter even in clinical trials, for example for MRI imaging weighted with the average (apparent) self-diffusion coefficient (ADC). The distributions of the self-diffusion coefficient, D measured for native blood plasma, are shown in Figure 3.2. For the three volunteers (V1, V2 and V3) the distribution of D is shown in Figure 3.2a, while Figure 3.2b shows the distributions measured for the seven samples of native blood plasma belonging to patients with colorectal cancer. In all cases, the appearance of two or more peaks can be observed, one of them being the main peak located from about $2.52 \times 10^{-9} \text{ m}^2/\text{s}$ to $\sim 4.31 \times 10^{-9} \text{ m}^2/\text{s}$ and another lower peak (or two peaks in the case of volunteer V1) is at high values of D . In principle, the main peaks are associated with relatively free water molecules.

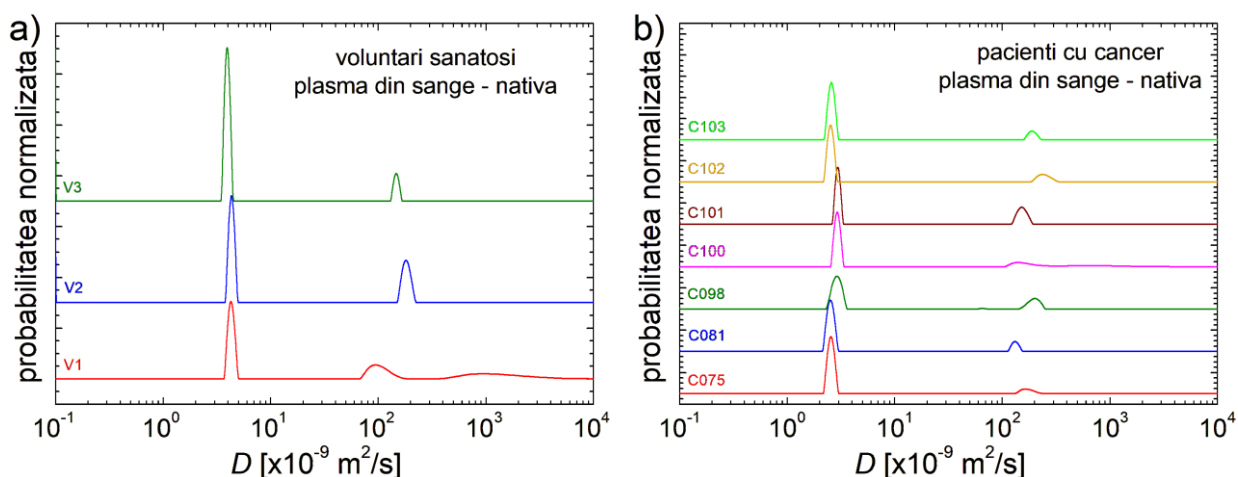

Fig. 3.2. The distribution of self-diffusion coefficient D measured by MRI of ^1H for a) healthy volunteers and b) patients with colorectal cancer.

Fig. 3.3. Values of the ^1H self-diffusion principal (*main*) coefficient measured by MRI for healthy volunteers (V1-V3) and colorectal cancer patients (C31-C103)

In our case, for blood plasma belonging to healthy volunteers, these peaks are located at values higher than $3.9 \times 10^{-9} \text{ m}^2/\text{s}$ as read in Figure 3.2a. Lower D -values are observed measured from the position of the main *peaks* for cancer patients (see Figure 3.2b). More precise measurements of the maximum of these main peaks are shown in Figure 3.3. For healthy volunteers, three measurements can be observed at values above $3.9 \times 10^{-9} \text{ m}^2/\text{s}$ (3.94 , 4.28 and $4.32 \times 10^{-9} \text{ m}^2/\text{s}$). In contrast, for cancer patients, the highest value (at which the maximum distribution of the main peak is obtained) D_{main} has values lower than $2.95 \times 10^{-9} \text{ m}^2/\text{s}$.

CHAPTER 4 CHARACTERIZATION OF BLOOD PLASMA BY FT-IR SPECTROSCOPY

4.1 Pilot Study 1

4.1.1 FT-IR spectra for native plasma

Fourier transformation infrared spectroscopy (FT-IR) is a powerful method for identifying compounds in samples to be studied. Thus, by analyzing FT-IR spectra, information related to the chemical bonds of specific biomarkers can be obtained [32]. Figure 4.1a shows the comparative FT-IR spectra measured for the blood plasma of healthy volunteers. It can be seen that FT-IR spectra are relatively simple. Thus, in the range of $3000\text{--}4000\text{ cm}^{-1}$, a high peak *is observed*, with a large integrated area, which can be associated mainly with water in the blood plasma. There is also a small and wide peak centered around 2085 cm^{-1} . In the range of specific frequencies, which are usually associated with characteristic functional groups (from 350 to about 1800 cm^{-1}), there are found (see Figures 4.2): i) a *high peak*, with a large integrated area, centered around 1644 cm^{-1} associated with Amida I; ii) a small peak centered around 1552 cm^{-1} associated with Amida II; iii) a series of peaks small bands, which are centred at 1461 cm^{-1} , 1400 cm^{-1} and which can be associated with the symmetrical stretching of COO^- belonging to glutamate and aspartate-like amino acids and with the symmetrical bending modes of methyl, CH_3 groups in proteins; iv) a very small and wide peak, centred around 1243 cm^{-1} associated with asymmetrical stretching; v) a wide band centred around $567\text{--}577\text{ cm}^{-1}$, which is usually neglected in the analysis of blood plasma specific to patients with colorectal cancer [32].

In the most important aspects, it can be said that the spectra recorded for healthy volunteers are similar to each other.

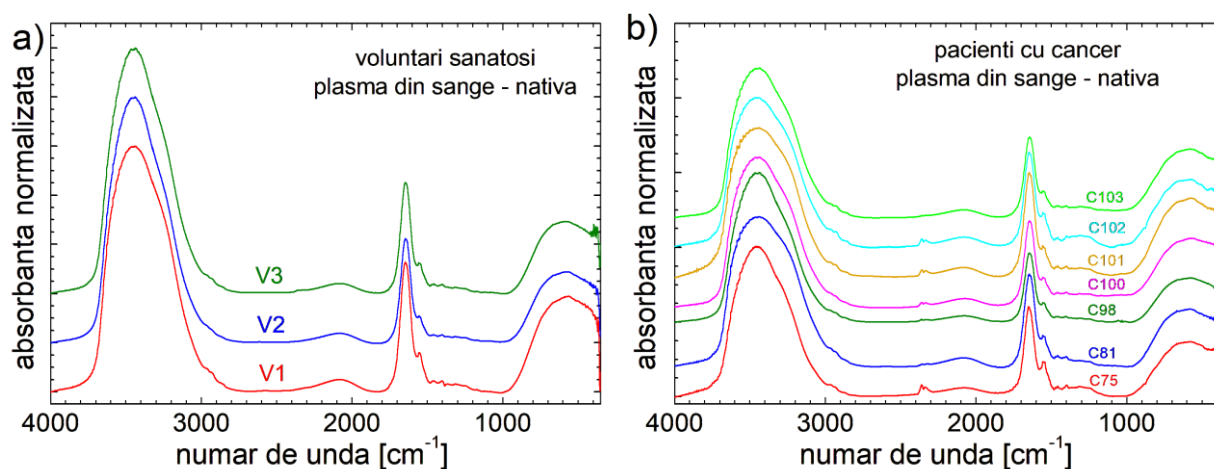

Fig. 4.1. Blood plasma FT-IR spectra measured for a) healthy volunteers (V1-V3) and b) colorectal cancer patients (C75-C103).

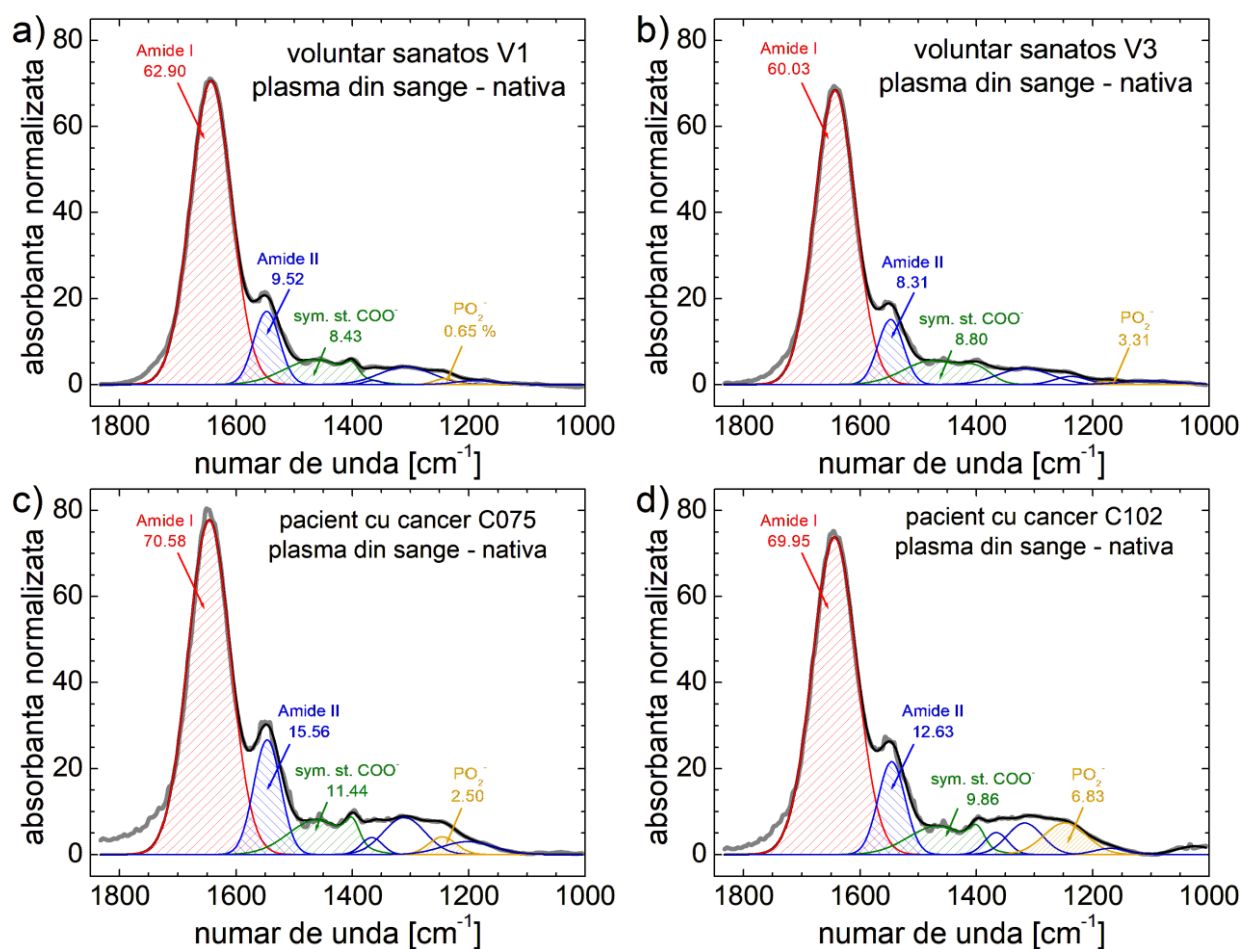

Fig. 4.2 Deconvolution of FT-IR spectra measured for native plasma collected from healthy volunteers a) V1 and b) V3 and for colorectal cancer patients c) C075 and d) C102. The integral area corresponding to Amide I, Amide II extends symmetrically from COO⁻ and are shown. PO_2^-

4.1.2 FT-IR spectra for deproteinized plasma

The FT-IR spectra recorded for deproteinised blood plasma collected from healthy volunteers are shown in Figure 4.3a. The deproteinization process takes place in the presence of methyl alcohol, which is why the FT-IR spectrum has some specific characteristics. In these cases, it can be said that the FT-IR spectra measured for the deproteinized blood plasma of the three volunteers are similar. The FT-IR spectra measured for the deproteinized blood plasma of the seven colorectal cancer patients are shown in Figure 4.3b. The specific associations of these peaks for the FT-IR spectrum shown in Figure 4.4 have been detailed in subchapter 4.1.1.

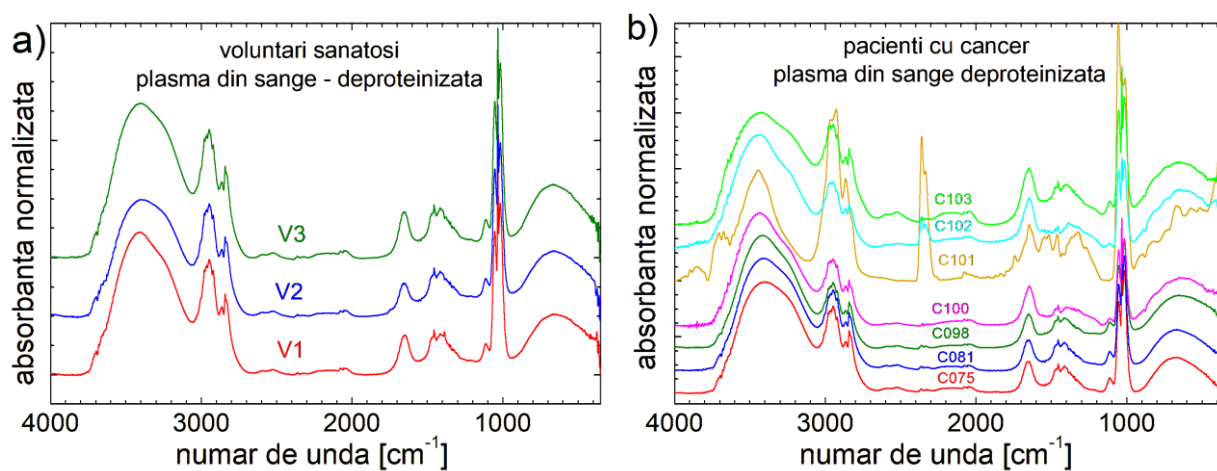

Fig. 4.3. FT-IR spectra of deproteinized blood plasma measured a) healthy volunteers (V1-V3) and b) colorectal cancer patients (C75-C103).

CHAPTER 5 ASSESSMENT OF HEALING 7 DAYS AFTER SURGERY

5.1 Specific preoperative and postoperative medical data

For this study, we used data from a group of 20 healthy volunteers, aged between 26 and 65 years (mean age was 52 years), with no history of cancer, and 10 patients diagnosed with colorectal cancer (both men and women), aged between 45 and 81 years (mean age being 67.6 years).

Several variables were considered, including age, neoadjuvant treatment, weight, diabetes, anaemia, Rayan score, haemoglobin levels before and after the seven days, among others, and these data are presented in Table 5.1. A key aspect of the study was the Rayan score, which is determined based on histopathological analysis and can last between four and six weeks. This was a crucial indicator, as it allowed the correlation of the results obtained by MRI methods and FT-IR spectroscopy, thus validating the accuracy and applicability of these techniques. Below in table 5.1 are presented all the data collected from the 10 patients with colorectal cancer.

Table 5.1 Social and clinical parameters of the patients studied (P1 to P10) [33].

5.2 Comparative analysis of native plasma in the blood by MRI relaxometry methods

Transverse relaxation time distributions, T_2 measured for native blood plasma collected from P1 to P5 patients with colorectal cancer presented as a pair of preoperative (red) and postoperative 7 days postoperatively (green) are shown in Fig. 5.1; while the distributions of T_2 measured for patients from P6 to P10 are shown in Figure 5.2. The measurements were made with two echo times ($TE = 70 \mu s$ – left and $TE = 500 \mu s$ – right). The experimental values were thus chosen to observe *the peaks that occur at a small T_2 relaxation time (low TE) and to clarify the peaks that occur at high T_2 values (high TE)*. A small echo time, TE will artificially widen *the peaks that occur at high T_2 values*, while a high TE value will filter out rapidly falling MRI signal components (*low T_2 values*). As a general remark, four peaks can be observed: i) three of them located at T_2 values below 20 ms (for $TE = 0.07$ ms) and ii) one, the main peak, located at T_2 values greater than 600 ms (see the figures on the right with $TE = 0.5$ ms). From left to right (i.e., from *lower T_2 values to higher values*), *peaks* describe components of native blood plasma (containing 1H) with increasing mobility. These components can be referred to as rigid, semi-rigid, intermediate, and mobile. As expected, the largest amount of 1H is localized in the most mobile components, most likely water in the blood plasma. Distilled water peaks in *the T_2 distribution* at about 3 s. If some dissolved fractions are present in the water, then the corresponding *peak* is shifted to lower T_2 values [33].

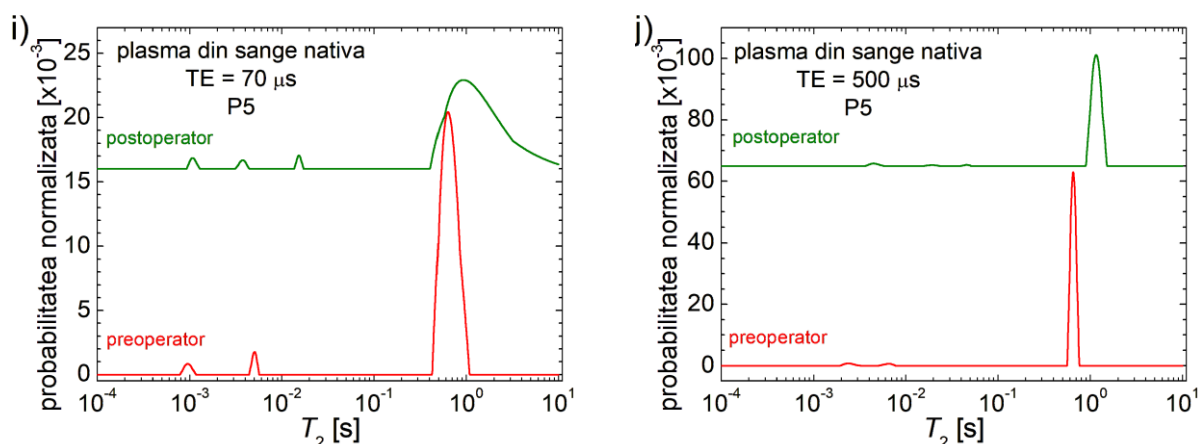

Fig. 5.1 T2 distributions measured with two values of echo onset time, TE = 70 μ s and 500 μ s for native blood plasma collected from patients a) and b) P1; c) and d) P2; e) and f) P3; g) and h) P4; i) and j) P5; with preoperative (red) and postoperative colorectal cancer 7 days after surgery (green).

5.3 Comparative analysis of blood plasma by FT-IR spectroscopy methods

Unlike ^1H MRI relaxometry, where the Laplace-type spectra (*T2 distributions*) are interpreted according to the position of the peaks correlated with the molecular dynamics influenced by the components (soluble and insoluble fractions), in the case of Fourier transform infrared spectroscopy (FT-IR), the concentration of a specific component (the vibration of the molecular bond occurring at a well-defined wavenumber) is directly proportional to the the amplitude of the measured peak. In this situation, FT-IR spectra measured for native and deproteinized blood plasma collected from 20 healthy volunteers could be mediated. These FT-IR spectra are shown in Figure 5.2 for native blood plasma. and for deproteinised plasma (blue line), together with FT-IR spectra measured for deproteinised plasma collected preoperatively (red) and postoperatively (green). Compared to the FT-IR spectra measured for deproteinized plasma, those measured for native plasma are simpler (see Fig. 5.2). A number of 5 distinct regions can be noted [247]: i) a wide *peak* between approx. 350 – 1000 cm^{-1} ; ii) a region with low absorbance between about 1000 – 1500 cm^{-1} ; iii) a narrow *peak* with the right shoulder between approx. 1500 – 1800 cm^{-1} ; iv) a wide *peak* with low amplitude between about 1850 – 2500 cm^{-1} and v) a *peak* between approximately 2700 – 3800 cm^{-1} .

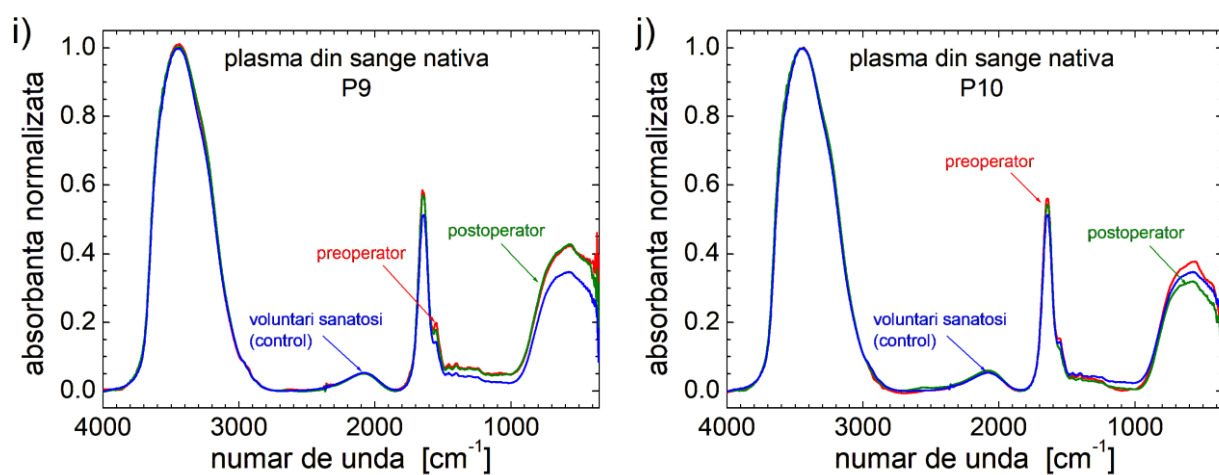

Fig. 5.2 FT-IR spectra measured for native blood plasma collected from patients a) P1, b) P2; (c) P3, (d) P4; (e) P5, (f) P6; (g) P7, (h) P8; i) P9 and j) P10; with preoperative (red) and postoperative colorectal cancer at 7 days postoperatively (green) compared to FT-IR spectra mediated for 20 healthy volunteers.

CHAPTER 6 PRINCIPAL COMPONENT STATISTICAL ANALYSIS OF SPECIFIC PARAMETERS FOR THE IDENTIFICATION OF METABOLITES IN BLOOD PLASMA AND ARTIFICIAL INTELLIGENCE

6.1 PCA Analysis Used for Identification of Colorectal Cancer in Blood Plasma Using Fourier Transform Infrared Spectroscopy (FT-IR) Measurements and Relaxometry and Nuclear Magnetic Resonance Diffusion of ^1H

6.1.1 Specific parameters for PCA analysis

From a practical point of view, the distributions generated by MRI of the T_2 transverse relaxation time and the self-diffusion coefficient D , but especially the FT-IR spectra, present some characteristic features that are not so easy to quantify for a definitive classification in the category of healthy volunteers or patients with colorectal cancer. Indeed, in the pilot study presented in chapters 3 and 4 it was possible to identify such features as the appearance of a small *peak* for all colorectal cancer patients in the T_2 distributions measured for deproteinized blood plasma, or the main value of the self-diffusion coefficient, D_{main} which was found in a range (below $2.95 \times 10^{-9} \text{ m}^2/\text{s}$) for colorectal cancer patients and in another range (over $3.9 \times 10^{-9} \text{ m}^2/\text{s}$) for healthy volunteers, but these are generally particular cases. Thus, for a statistical analysis, it is often necessary that the measured data be prepared for this purpose.

Apart from age and the main value of the self-diffusion coefficient, D_{main} a numerical deconvolution procedure applied to FT-IR spectra can lead to another set of quantifiable parameters. Thus, for example, Figure 6.1 shows FT-IR spectra measured for two healthy volunteers (see Figures 6.1a and 6.1b) and two patients with colorectal cancer (see Figures 6.1c

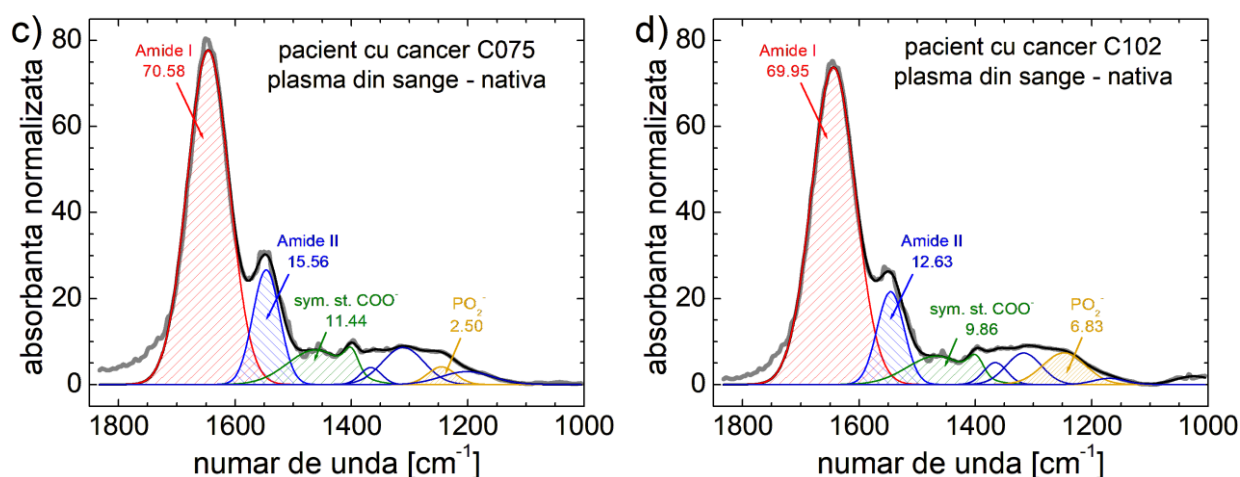

Figura 6.1 Deconvoluția spectrelor FT-IR măsurate pentru plasma nativă colectată de la voluntari sănătoși a) V1 și b) V3 și pentru pacienții cu cancer colorectal c) C075 și d) C102. and 6.1d) in the wavenumber range from 1850 cm^{-1} to 1000 cm^{-1} . Together with the measured spectrum (gray spectra represented with thicker line), the deconvolution results consisting of a sum of eight Gaussian functions (spectra represented with black lines) as well as each individual Gaussian function (represented with different colors in Figure 6.1) are presented.

The T_2 relaxation time distributions measured by MRI of ^1H show a variable number of peaks depending on the experimental conditions or the health status of the patients/volunteers. So it was decided to simplify the analytical procedure and eliminate this inconvenience. Therefore, in order to quantify with a single number each distribution of the transverse relaxation time, T_2 that should be used in a PCA analysis was calculated the mean ($T_{2,\text{av}}$) using the relationship [34],

$$T_{2,av} = \frac{\int_0^{\infty} f(T_2)T_2 dT_2}{\int_0^{\infty} f(T_2) dT_2}. \quad (6.14)$$

Calculated $T_{2,av}$ values are presented in Table 6.1, for all volunteers and patients with colorectal cancer for T_2 distributions measured for native and deproteinized blood plasma and blood plasma proteins. They are also used as input values for statistical analysis in the main components. The age of colorectal cancer volunteers/patients, MRI parameters and FT-IR parameters, which are presented in Table 6.1 are used together for statistical analysis in the main components [29].

6.1.2 PCA analysis results

The main result of the PCA statistical analysis, a scatter plot of PC1 versus PC2 values is shown in Figure 6.2. As mentioned before, PCA analysis involves a special type of graphical representation in which several types of parameters (usually with different units of measurement) can be represented together with the aim of separating data belonging to different groups (classes), but at the same time, if the chosen parameters are relevant, lead to a coagulation (grouping) for data points belonging to the same group [29].

Figure 6.2 PC1 versus PC2 graph from the principal components analysis.

6.2 Analysis of PCA, ROC and AUC values used to assess healing after surgery in patients with colorectal cancer

6.2.1 PCA Analysis

As shown in the previous subchapter, to analyze the effective PCA, of great importance, in addition to the position of *peaks* is the integral area of *peaks*. Such PCA analysis (correlated with ROC and AUC values) applied directly to FT-IR spectra is used to assess healing after surgery in patients with colorectal cancer. In order to quantify the intensity of FT-IR spectra, a different strategy was adopted than the one described above. It has been observed that the deconvolution procedure and quantification of each particular *peak* is time-consuming. Alternatively, a principal component statistical analysis (PCA) can be applied directly to the FT-IR spectra which involves only a transposition of the original data recorded as two columns (the first with the values of the wavenumbers and the second with the absorbance) into a single line representing the measured value of the absorbance of the FT-IR spectrum and the wavenumbers representing the measured parameters. This creates a matrix that has the number of columns equal to the number of measured values for the wavenumbers, and the number of lines is equal to the number of FT-IR spectra measured.

In Figure 6.3a, the evolution from preoperative to postoperative is marked with a dotted arrow for each patient. The arrow is black if the evolution goes from low PC1 values to high PC1 values and red if it goes in the opposite direction. The quantification of the different behaviors in the native blood plasma (Fig. 6.3a) shows: i) a small evolution as in the case of P9 which remains isolated at PC1 and PC2 negative; ii) an evolution towards the cluster of healthy clusters as in the case of P10 and P8; iii) the evolution to a new state (at PC1 and PC2 positive) represented by many postoperative individuals as in the case of P1, P2, P3, P4, P5 and P6; and iv) small evolution to an area of uncertainty as in the case of P7, which (in terms of FT-IR spectra measured for native blood plasma) postoperatively in the first approximation is similar to healthy volunteers V16 and V17 and in the second approximation to preoperative P8 and P2.

În Figura 6.3b se poate observa faptul că un grup mare de simboluri este localizat la valori ale lui PC1 negative este format din voluntari sănătoși, și cazuri preoperatorii și postoperatorii. Se poate observa o altă zonă la numere PC1 pozitive unde avem doar două simboluri preoperatorii aparținând pacienților mai discutați P5 și cei de mai sus identificați ca pacient izolat P9. Componenta PC2 nu pare să fie capabilă să inducă o separare. În PC1, poziția în spectrele FT-IR cu influență mai mare de 90 % se găsește în intervalele de: i) de la ~ 500 până la $\sim 850\text{ cm}^{-1}$; ii) de la ~ 1000 până la 1050 și ~ 1080 până la 2020 cm^{-1} (aparținând întinderii C-O); iii) de la ~ 1350 până la $\sim 1600\text{ cm}^{-1}$ (întinderea simetrică a P-O-C, întinderea simetrică a grupurilor funcționale COO-PO_2^- și Amidei II); iv) de la ~ 2000 până la $\sim 2300\text{ cm}^{-1}$ (de multe ori neobservat sau observat ca o

Figure 6.3 PCA analysis of FT-IR spectra measured for a) native and b) deproteinized blood plasma.

combination of restricted rotation and bending of the O-H bond (in water) [248]); and v) from ~ 2400 to $\sim 3700 \text{ cm}^{-1}$. Basically, FP1 was influenced by the entire relevant FT-IR spectrum. In this case, several types of developments can be observed: i) small developments within the non-discriminatory area as in the case of P4, P7 and P10; ii) medium developments as in the case of P3 going into the non-discriminatory cluster or P5 entering an area populated by healthy volunteers and postoperative patients; and iii) large developments as in the case of P2, P1, P6 and P8 moving from the non-discriminatory cluster to the healthy zone for healing and P9 moving from the extreme right zone to the healthy zone for healing.

6.2.2 ROC curves and AUC values

Compared to the PCA analyses performed on deproteinized blood plasma, the ROC curves show that the PCA analysis performed on native blood plasma separates the four ad-hoc groups much better. This can be seen from the corresponding AUC, where for PC1 obtained for native blood plasma (see Figure 6.4a) values between 0.576 (native versus colorectal cancer pre – before

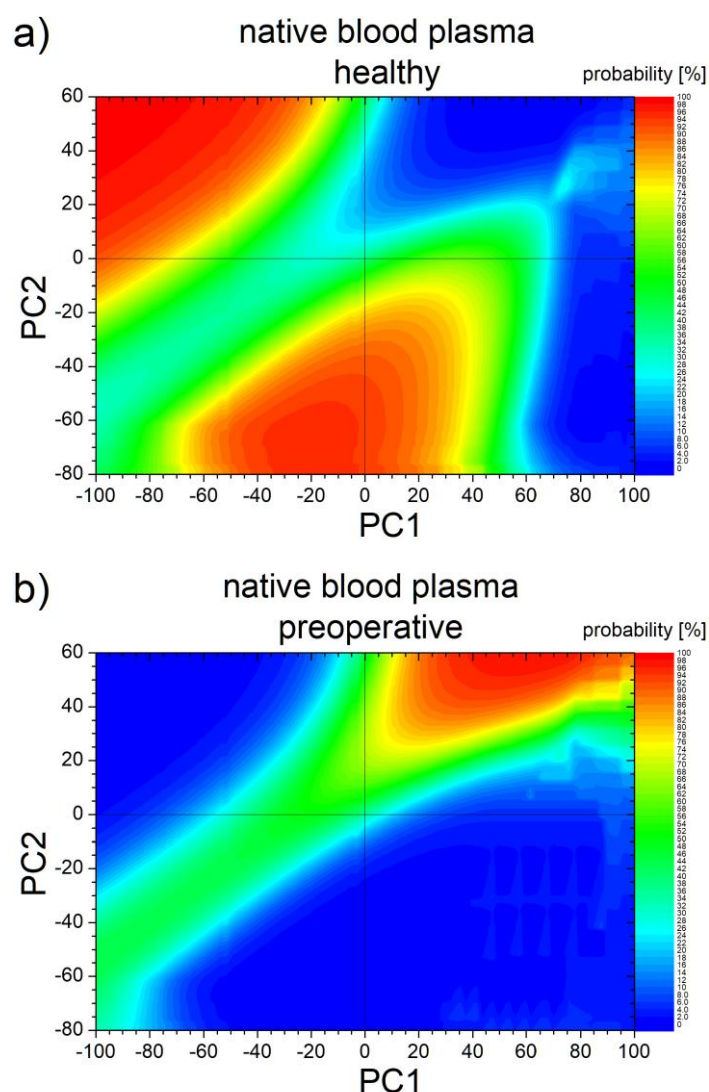

Figure 6.4 ROC curves calculated from PCA analysis data of FT-IR spectra measured for native blood samples for PC1 (green curve) and PC2 (brown curve) taking into account the analyzed pairs: a) healthy (positive) versus CRC (preoperative – preoperative and postoperative – post); b) healthy (positive) versus CRC (preoperative – pre), c) healthy (positive) versus CRC (postoperative – post) and d) CRC (preoperative – pre) (positive) versus CRC (postoperative – post). Optimal *cutting points* are indicated for both PC1 and PC2 parameters. The values of the areas under the curve (AUC) are also indicated.

surgery) and 0.67 (colorectal cancer – pre versus colorectal cancer – postoperatively). The fact that PC1 (with the highest relevance) shows a high AUC value, comparing native blood plasma collected from patients with preoperative and postoperative colorectal cancer indicates that a certain evolution is observed after surgery (here, the optimal *cut-off point* was located at 0.7 sensitivity and 0.3 specificity). The expected prediction was that the clearest separation would be observed between the group of healthy volunteers and the group of patients with preoperative colorectal cancer (with specificity/sensitivity 1 of 0.4/0.6). The highest AUC value (0.694) was obtained for the PC2 component in the evaluation of healthy volunteers versus postoperative colorectal cancer patients. This is a clear indication that the healing process is not oriented towards a state described by healthy volunteers and, in this way, supports, once again, the existence of a *distinct* post-operative state. Unless the analysis of native blood samples taken from preoperative and postoperative colorectal cancer patients is compared, for the rest of the cases, the AUC value measured for PC2 is higher than that measured for PC1.

6.3 PCA Statistical Analysis and Machine Learning Prediction

Comparing the two PC1 versus PC2 representations based on FT-IR spectra measured for native and deproteinized blood plasma (Figures 6.5), only one was chosen for prediction, namely the one resulting from the analysis of native blood plasma. The measured data (PC1 and PC2 coordinates) together with the corresponding label (healthy volunteers, preoperative CRC patients, postoperative CRC patients) constituted the input data with which the virtual machine was trained. After training an artificial neural network constituted virtually using software written for this purpose in JavaScript to which specific libraries were added. Each point in the rectangular area was considered a point in the image space (screen) and the trained artificial neural network was asked to predict the state: healthy, preoperative colorectal cancer or postoperative colorectal cancer. This classification is normalized, so the results for each class come as a probability. Probability maps for all three classes are shown in Figures 6.5.

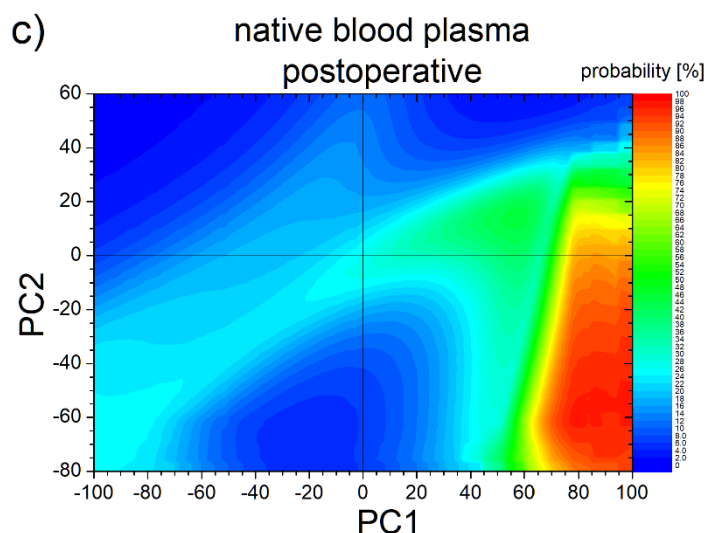

Figure 6.5 Machine learning used to predict the state of a) health; and the probability of CRC b) pre-operative and c) postoperative from the 2D PCA analysis of FT-IR spectra measured for native blood plasma.

The medium probabilities (30 – 70 %) surround the areas with high probability (see green), and the low probability (blue color) is found at high values of PC1 (zone I) and positive values of PC1 and PC2 (zone II). An increased probability (~ 25 %) can be observed compared to the surrounding points, and is found for values of about 70 – 80 for PC1 and 20 – 30 for PC2 due to the presence of V3. We expected an average probability along the entire quasi-diagonal area. The machine learning algorithm predicted an increased probability for positive values of PC1 and large values (> 30) of PC2.

Of real interest was the map predicted and associated with the measurement of FT-IR spectra on native blood plasma collected from colorectal cancer patients 7 days after surgery. This is because in the graph PC1 versus PC2 (see Fig. 6.3a) the points associated with this category do not form a separate cluster. But these points are in the vicinity of the points associated with one or two of the other category. Surprisingly, one can find an isolated area that is characterized by a high probability to locate postoperative patients. This can be found at high PC1 values and negative PC2 values. It is surprising, because in this area we have only one point, belonging to the postoperative P8. Moreover, the V6 is closer to that area than the P8. This artifact is more likely due to incomplete training. The rest of the map is credible and one can find a high probability (~40 – 70 % - green colors) for positive values for PC1 and positive values (up to ~30) for PC2 covering the area called *healing*. As mentioned before, at positive PC1 values (25 – 60) and negative PC2 values, we also have an increased probability (light blue to green) due to the presence of postoperative P8.

CHAPTER 7 IDENTIFICATION OF CANCEROUS COMPONENTS IN BLOOD PLASMA BY HIGH-RESOLUTION MRI SPECTROSCOPY

7.1 Spectrum analysis using the Processing interface and quantification of metabolites

The last step to quantify the metabolites in each MRI spectrum of ^1H recorded for blood plasma is to read it (using software written in ProcessingTM) as text, as obtained after export using the jMRUITM software. This software is developed by a group of researchers from the Technical University of Cluj-Napoca, in the last 10 years, and is specially dedicated to the analysis and quantification of the MRI spectra of ^1H recorded for tissues (*in vivo* or *ex-vivo*)

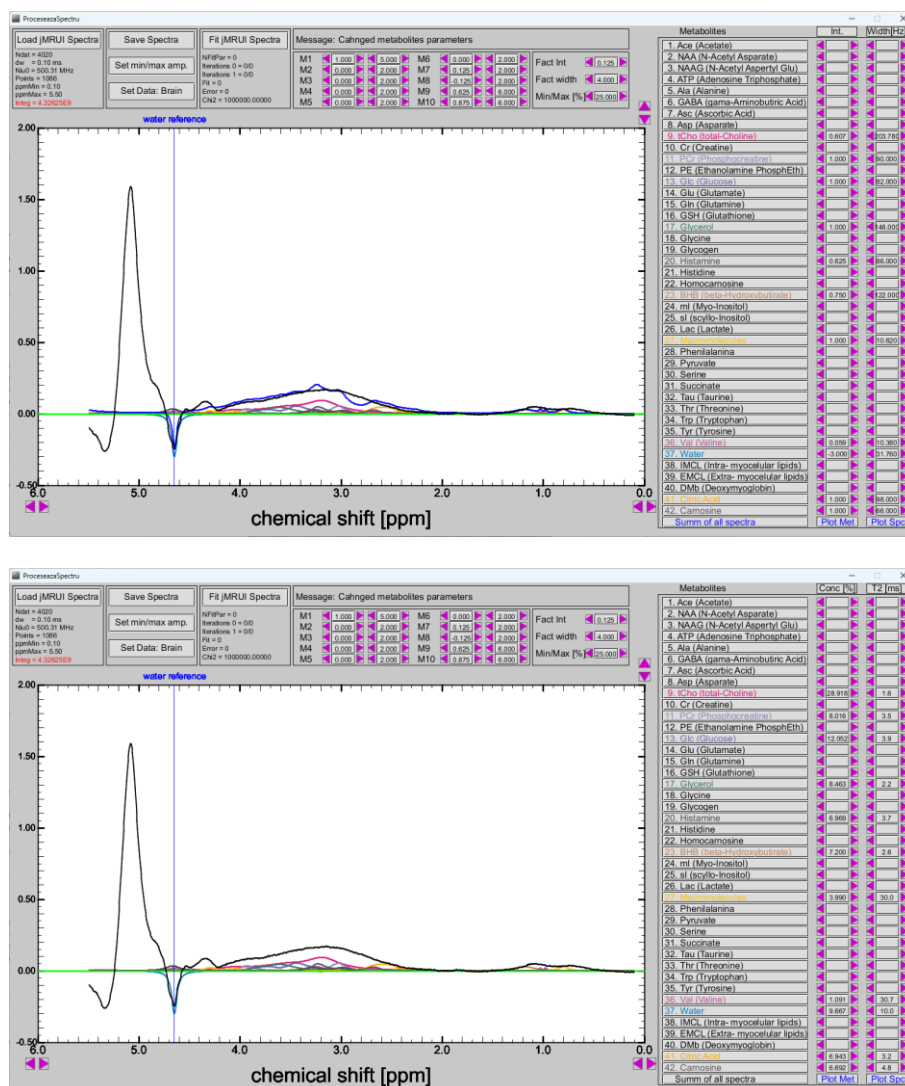

Figure 7.1. Captura de ecran cu fereastra softului Processing care prezintă spectrele RMN a ^1H înregistrate pentru plasma din sânge nativă, colectată de la pacienții P105 cu cancer colorectal și contribuția câtorva metaboliți identificați a) intensitate și lărgime de linie și b) concentrație și timpul de relaxare T_2 .

or biological materials (such as blood or blood plasma) and involving the presence of a large number of metabolites. The NMR spectra of ^1H for a total of 41 metabolites and water can be

simulated taking into account the total number of absorption lines and scalar couplings (J) between the nuclear spins. The intensity of each metabolite can be slightly modified, as well as the line width, a parameter that is related to the magnetic field that was used experimentally (its intensity and homogeneity). The effect of homogeneity (i.e. line width) was explored in subchapter 2.1.4, where for a number of metabolites the spectra for a line width at semi-height $\Delta\nu = 0.5, 1.0, 2.0$ and 4.0 Hz were presented. By pressing a button (*load jMRUI Spectra*) the NMR spectrum of ^1H is read from the corresponding file (exported from jMRUI and located in the Input directory of the basic program), and graphically represented with a black curve (see Figures 7.1). In the next step, the limits of spectrum representation (in amplitude and chemical displacement) are chosen. The software allows approximation of data with a sum of individual metabolite spectra using the Levenberg–Marquardt algorithm. To do this, press the *Fit jMRUI Spectra* button. Error and mean squared deviation (χ^2) are the parameters for evaluating the degree of approximation. This algorithm implies that for the values of the approximate parameters, an initial value must be given. And the convergence of the approximation (success rate) is most often conditioned by the choice of a set of values of the best parameters (initial approximation). The number of parameters to be approximated is large, for each metabolite the amplitude (or intensity) of the signal as well as the line width are taken into account. An uninspired choice most of the time leads to a non-convergence of the simulated spectrum to the measured one, but in certain cases it can lead to a divergence involving non-physical values for certain approximate parameters. Thus, for *data protection*, a procedure has been implemented that allows the parameters to vary only by a certain percentage around the initial approximation. Thus, the first step in initiating the approximation of the spectra is to choose, from the list presented in the right menu (see Figures 7.1), each metabolite in turn and to observe if it could be present in the measured spectrum. Metabolites for which the amplitude of the measured spectrum, at the values of the chemical displacements for which they are defined (for all these values), is zero or negligible, are eliminated. This feature, which allows the observation of the NMR spectrum of each metabolite for the entire definition range, is essential and is not implemented in any of the previously described software (ParaVision™ 360 v3.5, Bruker-TopSpin™ or jMRUITM), which is why they have not been used for quantification of metabolites. Thus, the presence of a metabolite from the measured NMR spectra cannot be affirmed if the spectrum characteristic of the metabolite cannot be presented as a deconvolution for the entire definition range (see Figure 7.7) and not only for single specific values, as presented by, for example, the ParaVision™ 360 v3.5 software.

CHAPTER 8 ADVANCED HIGH-FIELD MRI METHODS FOR THE ANALYSIS OF BIOPSIES HARVESTED FROM COLORECTAL CANCER PATIENTS

8.1 MRI imaging for the evaluation of biopsies taken from the colon and rectum area

8.1.1 *T1-encoded MRI images*

MRI images of some biopsies are not as spectacular as those recorded for whole organs. Figure 8.2 shows a series of such MRI images acquired as a series of 9 slices in sagittal section, using the *T1-FLASH* protocol, on the 11.7 T MRI tomograph measured 24 hours after biopsy for two tissues from the same colon in the area with cancer – top and healthy – down, collected from

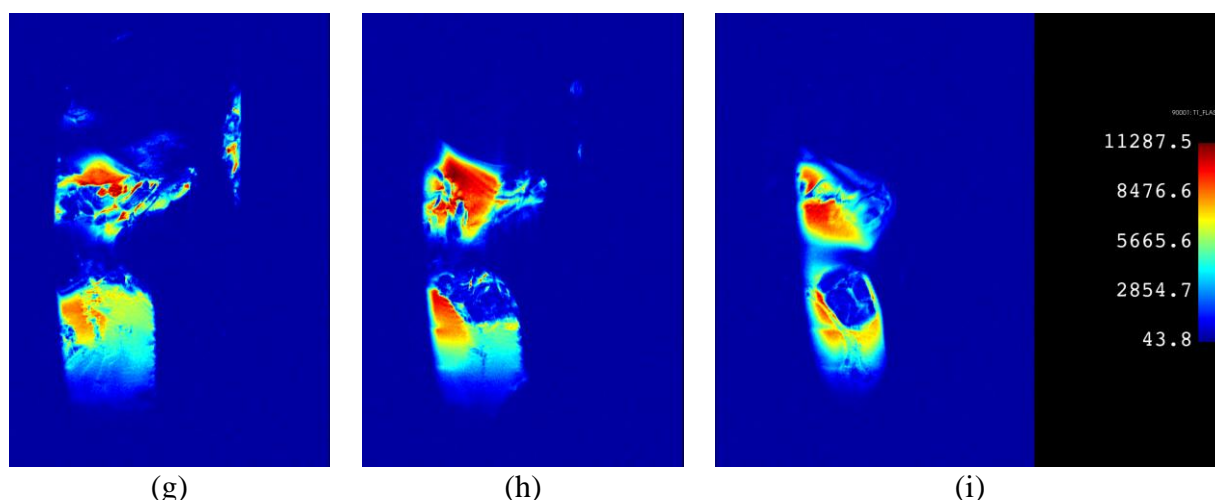

Figure 8.1. Images of 9 slices coded with T1 longitudinal relaxation time acquired using the *T1-FLASH* protocol at the BioSpec 11.7 T MRI tomograph for two tissues (with cancer – top and healthy – bottom) collected from a cancer patient measured 24 hours after biopsy.

a cancer patient. For a deeper interpretation of the images, it is necessary to know the anatomical components that make up the colon and that can be observed in axial section. Thus, for a complete section of a sigmoid colon (the area of the colon close to the rectum) one could observe the lumen, which is the empty space inside through which fecal matter passes *in vivo*. This component is not visible in the images presented in this chapter because the biopsy did not remove the entire colon. What can be seen in Figure 8.1 is the sigmoid colon wall. It is composed of four main layers: i) the inner layer (which secretes mucus in order to facilitate the passage of fecal matter) is called mucosa; ii) the next layer consists of a connective tissue (which contains blood vessels, lymphatic vessels and nerves) and which is called the submucosa; iii) the mucosa and submucosa are separated by a layer of mucosal musculature; iv) there is also a musculature of its own and which presupposes the existence of a muscular layer responsible for peristalsis (which represents the set of movements of the colon that lead to the movement of waste – fecal matter – to the rectum, and which, at the level of the large intestine, occurs with a reduced frequency of only a few times a day), and which has a circular (internal) and a longitudinal (external) component; v) the outer layer that appears as a serous membrane covering the sigmoid colon is called serous; vi) it is surrounded by the peritoneum; vii) On the outside there is a mesenteric adipose tissue: it surrounds the sigmoid colon and contains blood and lymphatic vessels that supply the colon. If we were to describe the mechanism of cancer invasion, then it can be said that initially, colorectal cancer remains limited to the internal area of the mucosa. Later it can invade the submucosa and the muscle layer. At this point, the risk of metastasis through the lymphatic and blood vessels is increased. In advanced stages, colorectal cancer can invade the serous and peritoneum, reaching the mesenteric vessels and from there to adjacent structures, which can be the bladder and ureters or the uterus in women.

8.1.2 T2-encoded MRI images

The most well-known MRI imaging times are those encoded with the T2 spin-spin relaxation time. Most of the time a small T1 spin-spin relaxation time is associated with a small T2 spin-spin relaxation time (but this is not a rule, especially as in the real case where we do not have a single value for these two relaxation times, $T1$ and $T2$, but a distribution of values, indicating the presence of components with complex molecular dynamics). Thus, in MRI images encoded with T2 spin-spin relaxation time, as is the case in Figure 8.2 and which were recorded using the T2-TurboRARE protocol at the 11.7 T BioSpec MRI tomograph, the more intensely colored areas will be described by a high value of T2 spin-spin relaxation time and/or a high value of spin density. In images 8.2a to 8.2f it can be seen that the area of the tumor tissue is represented by bluish colors and that they can be associated with MRI signal values that are up to 25% of the maximum values obtained (in these images – the values are represented as numbers in the internal system of the spectrometer without being able to indicate a more concrete unit of measurement) and that means that both the spin-spin T2 relaxation time, is small and the spin density is relatively (at other areas in the image) low. In contrast, the peripheral areas, which have been associated with the serosa, adipose tissue and blood and lymphatic vessels, are characterized by a high T2 spin-spin relaxation time as well as a high hydrogen density. It has its most likely source in water, which can be found in abundance in these layers of the sigmoid colon. At the same time, from figures 8.2c to 8.2f, it can be seen that healthy tissue is also characterized by MRI signals that are about 20-25% of the maximum values obtained and that can also be associated with a low spin-spin T2 relaxation time as well as with a relatively low spin density (1H). This makes it more difficult to identify colorectal cancer directly from such encoded images, with the T2 spin-spin relaxation time. This would require ignoring (from a practical point of view, saturating the images in the peripheral areas: serous, adipose tissue, and blood and lymphatic vessels) and obtaining improved contrast for the 15-25% areas of the signal. From this point of view, it can be said that the images encoded with the T1 spin-spin relaxation time, (as shown in Figure 8.1 recorded with the *T1-FLASH* protocol) show a better natural contrast (obtained without the use of contrast agents) than the images encoded with the T2 spin-spin relaxation time (as shown in Figure 8.3 and which were recorded using the T2-TurboRARE protocol). Otherwise, from both types of images, certain features can be observed that indicate the texture of the tissues, especially in the internal area of the clone, such as the mucosa and connective tissue. A clear advantage of MRI imaging techniques is that, once the tumor area is identified, it can be very well delimited, and therefore, quantified as spatial extent.

Figure 8.2. Images of 9 slices coded with T2 longitudinal relaxation time acquired using the T2-TurboRARE protocol at the BioSpec 11.7 T MRI tomograph for two tissues (with cancer – top and healthy – bottom) collected from a cancer patient, measured 24 hours after biopsy.

8.2. MRI spectroscopy of tumor tissue biopsy

In the MRI spectrum of high-resolution ^1H recorded in high fields (11.7 T) for tumor tissue, the presence of several metabolites is observed in addition to the spectrum recorded for healthy tissue. First of all, peaks with (relatively) high amplitudes, located at ~ 1.1 ppm and \sim

0.67 ppm as well as the series of peaks with lower amplitude, located in the range from ~ 1.7 ppm to ~ 3.3 ppm, are observed. Secondly, it was observed that the quantification results in a higher number of metabolites (to which macromolecules and water are added), which obviously lead to a change in the concentration as follows: i) water ($\sim 41.4\% \downarrow$); ii) adenosine triphosphate (ATP) ($\sim 11.38\% \downarrow$); iii) macromolecules, especially M1, M2 and M9 ($\sim 8.86\% \uparrow$); iv) alanine ($0\% \downarrow$); v) valine ($\sim 14.83\% \uparrow$); vi) intracellular lipids ($0\% \downarrow$); vii) ascorbic acid ($\sim 1.28\% \uparrow$); viii) glucose ($0\% \downarrow$); ix) lactate ($\sim 1.91\% \uparrow$); to which are added a number of new metabolites:

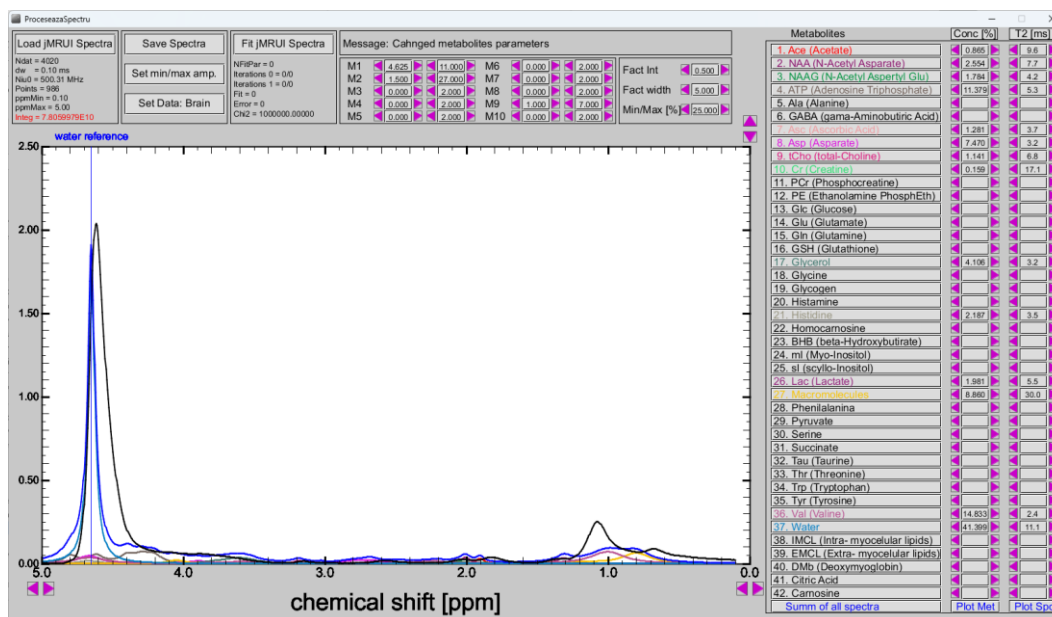

Figure 8.3. Screenshot of the Processing software window showing the MRI spectra of ^1H recorded for tumor tissue collected from a colorectal cancer patient and the contribution of several identified metabolites, their concentrations and T_2 relaxation time.

x) asparat ($\sim 7.47\% \uparrow$); xi) glycerol ($\sim 4.11\% \uparrow$); xii) NAA (N-acetyl aspartate) ($\sim 2.55\% \uparrow$); xiii) histidine ($\sim 2.19\% \uparrow$); xiv) NAAG (N-acetyl aspartyl glutamate) ($\sim 1.78\% \uparrow$); xv) total choline ($\sim 1.14\% \uparrow$); xvi) acetate ($\sim 0.87\% \uparrow$) and xvii) creatinine ($\sim 0.16\% \uparrow$). The estimated T_2 relaxation time for macromolecules remained the same (30 ms) but increased for water (11.1 ms). Otherwise, in general, T_2 relaxation time values have values between 2.4 ms (valine) and 9.6 ms (acetate), indicating a slight narrowing of the absorption lines in the MRI spectrum of ^1H of high resolution recorded for tumor tissue biopsy.

8.3 High-field MRI relaxometry

8.3.1 T_2 distributions obtained for tumor and healthy tissue biopsies

In the lower-right half are shown the CPMG drops obtained using the Bruker ParaVision 360 v3.5 software that operates the BioSpec 11.7 T MRI spectrometer. They were obtained from the sequence of 64 images recorded for a biopsy of a tissue (affected by colorectal cancer and a resection margin) located in the colon area. Along with the experimental data, the statistical errors

(mean values and the statistically obtained mean square deviation for all the voxels that make up each area of interest) are presented, as well as the approximation with a mono-exponential function (the only one available for the Bruker ParaVision 360 v3.5 software). Single values of T_2 relaxation times, measured for tumor tissue () and healthy tissue (). In the lower-central part there is a map (map) obtained as a value of the relaxation times $T_2^{\text{tumoare}} = 17.70 \text{ ms}$, $T_2^{\text{sănătos}} = 19.99 \text{ ms}$, measured in each voxel.

From the analysis of the approximation curves (fitting) of the experimental data, it is observed that these approximation can be characterized as deficient. Thus, it is necessary to implement another method of approximation of experimental data and which has been presented in the experimental program of this thesis, namely the analysis of CPMG curves using the inverse Laplace transform. The spin-spin relaxation time distributions of the 2 CPMG curves presented are comparatively represented in Figure 8.4. It is observed that tissues (both tumor and healthy) are characterized not by a dynamic component (as would result from the primary Bruker ParaVision analysis) but by 4 components with different molecular dynamics.

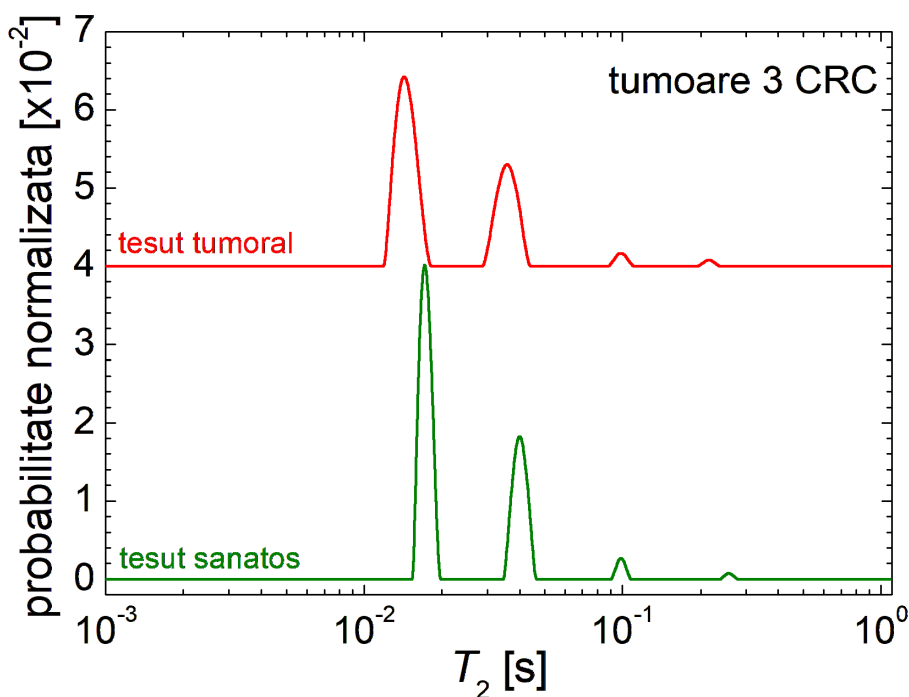

Figure 8.4. T_2 relaxation time distributions measured by MRI of ^1H recorded in high magnetic fields (*ex-vivo*) for biopsy of a tumor tissue (red) and a healthy marginal tissue (green), both collected from a colorectal cancer patient.

8.3.2 Mape parametrice de T_2 obținute pentru biopsii ale țesutului tumoral și sănătos

The ultimate goal of MRI relaxometry studies using images recorded in high fields is to obtain T_2 parametric maps obtained for biopsies of tumor and healthy tissue obtain parametric maps containing information about the location in space of the various *component parts* (tissues,

Figure 8.5. Parametric maps representing the spatial distributions of $T2$ relaxation time and spine density ($1H$) measured by MRI of $1H$ recorded in high magnetic fields (*ex-vivo*) from the echo train drop shown in Figure 8.7 for biopsy of a tumor tissue and a healthy marginal tissue, both collected from a colorectal cancer patient.

subsections of tissues, tissues with various characteristics – for example tumors) by obtaining a more relevant contrast between the area of interest and the adjacent areas.

CONCLUSIONS

1. A research plan was developed with the aim of performing a complex characterization of materials with biological origins such as fluids (blood plasma) and human tissues, both from patients diagnosed with colorectal cancer and from healthy subjects in the control group.
2. The selection criterion for colorectal cancer patients and healthy volunteers included in the study was rigorously defined, for which both relevant clinical and biological aspects and their compatibility with the research objectives were considered. The recruitment process involved the detailed evaluation of the medical history, biological parameters and inclusion and exclusion criteria, thus ensuring the validity and relevance of the results obtained.
3. Modern methods of relaxometry and diffusometry MRI of ^1H in low magnetic fields have been successfully used for the characterization of blood plasma (native, deproteinized as well as plasma proteins), being initially applied to a small batch of samples in a pilot study, and later extended to a larger batch of samples, in order to obtain more robust and representative results in an extended study.
4. It has been shown that the main values of the self-diffusion coefficient, D can be successfully used to differentiate native plasma biological samples from colorectal cancer patients from healthy volunteers.
5. FT-IR spectroscopy proved to be an effective method for complex characterization of the same blood plasma components, being initially applied to the same small batch of samples in the pilot study, and later extended to a larger batch, in order to validate and consolidate the results obtained.
6. It has been demonstrated that modern methods of ^1H MRI relaxometry and FT-IR spectroscopy applied to sets of blood plasma samples from patients with colorectal cancer can be successfully used to assess the degree of cure at 7 days after surgery and, if correlated with statistical and machine learning methods, can be used as methods to predict healing after surgery.
7. The complex data analysis was a detailed procedure that involved the implementation of several steps, starting from the primary processing of the raw data obtained by FT-IR spectroscopy measurements and ^1H MRI relaxometry and diffusometry, followed by the Fourier transform and the inverse Laplace transform to obtain the Fourier or Laplace spectra

(spin-spin relaxation time distributions, T_2 or the self-diffusion coefficient, D) as well as their deconvolutions. In the quantitative analysis stage, statistical tools were used to evaluate and interpret the parametric values and spectra obtained. Finally, the process was completed with advanced statistical analysis, using the principal component analysis (PCA) technique, which was improved by integrating artificial intelligence algorithms. This included the use of artificial neural networks and machine learning techniques to identify patterns and extract meaningful insights from complex datasets.

8. The PCA analysis applied to native blood plasma provides a significantly clearer separation of the four groups formed *ad-hoc*, compared to the similar analysis performed on deproteinized blood plasma, as indicated by the ROC curves. This idea has also been expressed by the ^1H MRI diffusometry measurements showing that for differentiating the specific characteristics of colorectal cancer, there is no need to use deproteinized plasma that requires a longer preparation time, additional technique, and reagents that can lead to an increase in the complexity of the measured spectra correlated with an increase in the difficulty of interpretation.
9. It has been proposed to use MRI spectroscopy of ^1H in high fields (7 T and 11.7 T) to identify cancer-associated components in blood plasma, allowing a detailed and precise analysis of the metabolites present. This advanced method provided valuable insights into the specific metabolic changes associated with the presence of cancer cells.
10. MRI imaging, spectroscopy and relaxometry of ^1H in high fields has been successfully used for the analysis of biopsies harvested from patients with colorectal cancer, allowing the identification and characterization of metabolic compounds in tumor tissues and healthy tissue, thus contributing to the accurate diagnosis and deeper understanding of the pathological processes associated with this disease.

Detection., 33th Annual Conference of the European Society for Biomaterials ESB, 4-8 September 2023, Davos, Switzerland. – Poster.

2. **L R Dragan**, D Andras, Ioana A. Pop, A Farcasanu, C. Saitis, R. Crainic and R Fechete, Spectroscopic NMR and FT-IR approach used for the evaluation of healing after surgical interventions for patients with Colorectal Cancer, 13th biennial International Conference on Processes in Isotopes and Molecules PIM-INCDTIM, 19-22 September 2023, Cluj-Napoca, Romania - Poster.

LIST OF PUBLICATIONS OUTSIDE THE FIELD OF THE THESIS

Papers published in ISI indexed journals

1. **L. R. Dragan**, E. Jumate, C. Aciu, D. L. Manea, R. Fechete, Advanced characterization of plastering mortars with glass waste additives, AIP Conference Proceedings 2206 (1), 030005, (2020).
2. Catalin Saitis, Daniela Lucia Manea, Monica Luminita Plesa; **Raluca Lavinia Saitis**, Recycling, Plaster Waste as a Substitute for Aggregates in Obtaining Plastering, Mortars. Buildings 2023, 13, 491. <https://doi.org/10.3390/buildings13020491>.

Papers published in non-ISI journals

1. **Lavinia R. Dragan**, Ramona Crainic, Radu Fechete, A comparative study for natural degradation of three local anesthetic drugs for human use by ^1H nmr relaxometry and ft-ir spectroscopy. Studia Universitatis Babes-Bolyai, Physica 63, 61-73 (2018).
2. Ramona Crainic, **Lavinia R. Dragan**, Radu Fechete, ^1H NMR relaxometry and ATR-FT-IR spectroscopy used for the assesment of wastewater treatment in slaughterhouse, studia universitatis babes-bolyai, physica 63, 49-60 (2018).

Papers presented at international conferences

1. **L. R. Dragan**, E. Jumate, C. Aciu, D. L. Manea and R Fechete, Advanced characterization of plastering mortars with glass waste additives, 12th biennial International Conference on Processes in Isotopes and Molecules PIM-INCDTIM, 25-27 September 2019, Cluj-Napoca, Romania - Poster.
2. R. Fechete, R. Crainic, **L. R. Dragan**, D. Moldovan, R. I. Chelcea, The perspectives of numerical neuroevolution of artificial neural networks with applications to Fourier and Laplace-like spectroscopy, 14th biennial International Conference on Processes in Isotopes and Molecules PIM-INCDTIM, 19-22 September 2023, Cluj-Napoca, Romania - Poster.
3. Ramona Crainic, Alexandru Stefan Farcasanu, Petru Pascuta, **Lavinia Raluca Saitis**, and Radu Fechete, Advanced experimental and numeric simulation method used for the characterization of nanofibers biomaterials produced by electrospinning. 33th Anual

Conference of the European Society for Biomaterials ESB2023, 4-8 September 2023,
Davos, Switzerland - Poster.
